# Open Phase Failure on the HV-Side of Power Plants Requires New Protection Solutions

## Table of content

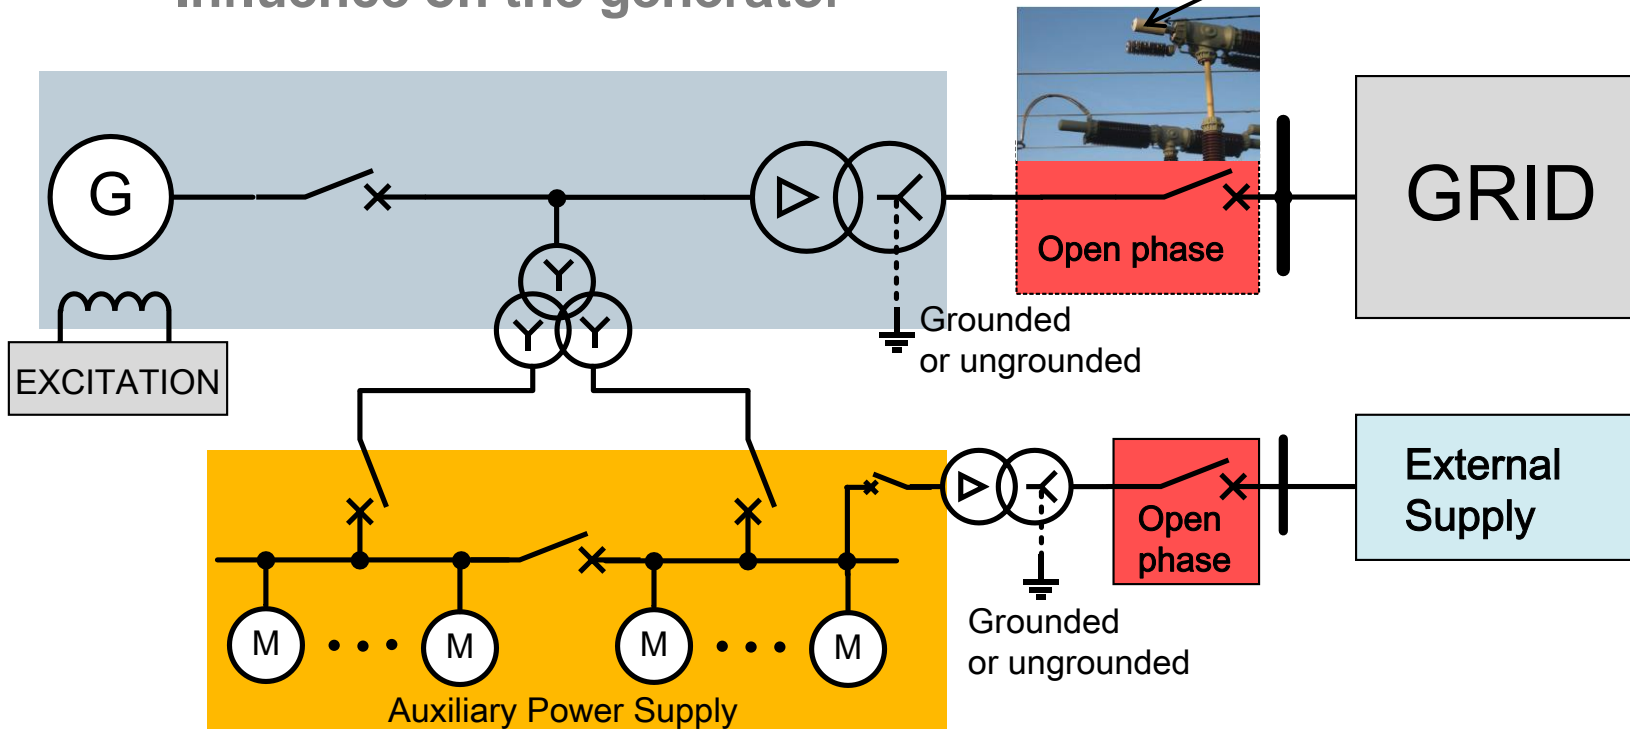

- **Introduction of open phase failure**
- **Influence on the generator-transformer unit**
  - **Proposal for an additional protection**
- **Influence on the auxiliary power supply**
  - **Discussion of the problem**
  - **Proposal for a protection solution**

# Power system structure and open phase failure situation

## Two main topics

### Influence on the generator

Broken connection to the CB

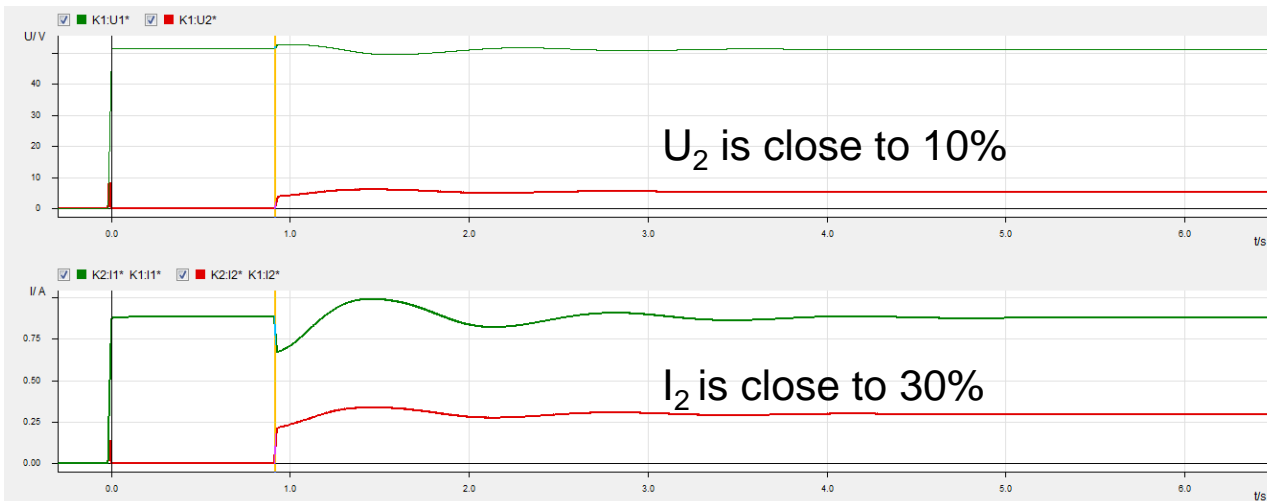

## Byron Failure

### Influence on the auxiliary power supply

# Influence on generator (one open phase failure) Grounded transformer neutral point

After a short transient period there are stable conditions  
(depending on the load and settings overcurrent protection can pickup in one phase)

Measurable negative sequence voltage

A higher negative sequence current flows. Thermal negative sequence protection trips after seconds  
( $I_2^2 * t = 5 \text{ s} \rightarrow \text{trip after } 55,5\text{s}$ )

# Influence on generator (one open phase failure) Isolated transformer neutral point

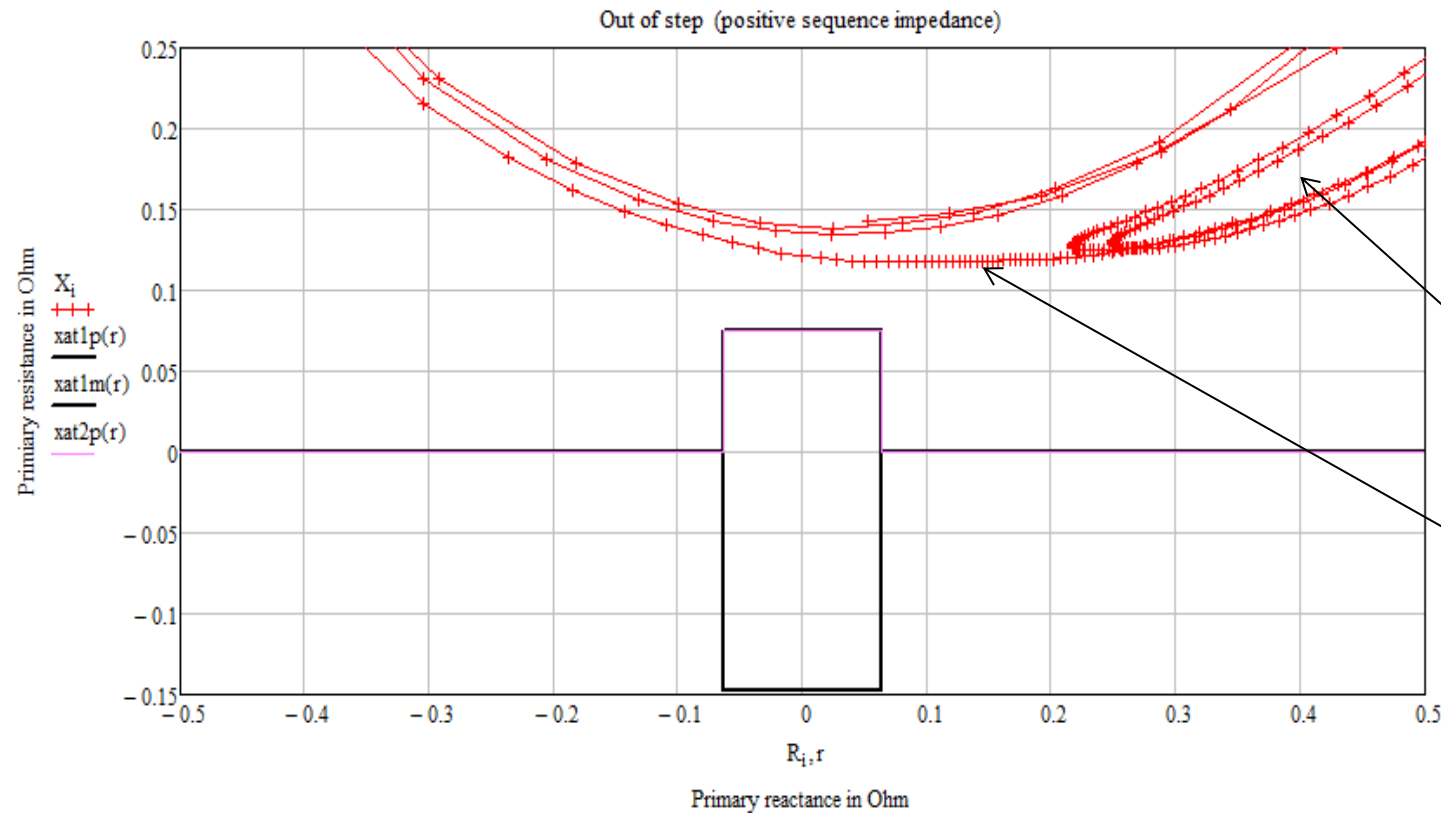

The generator becomes instable and after few seconds an asynchronous condition occurs

High negative sequence voltage, but the voltage swings (a chattering of a  $U_2$ -function is possible)

High negative sequence current; he swings synchronous with the positive sequence current ( $I_2$ -protection trips too late)

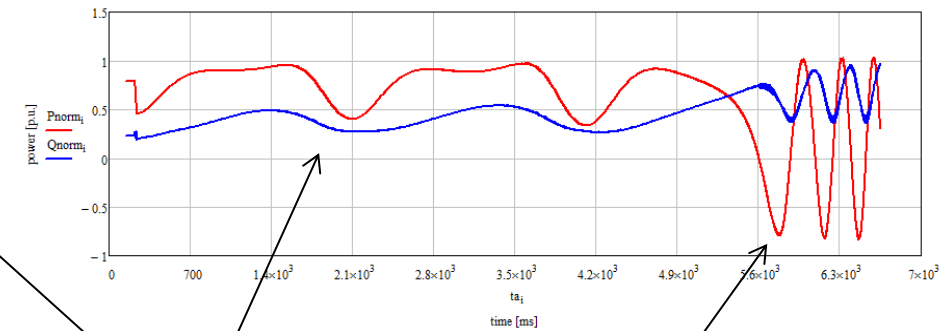

# Influence on generator (one open phase failure) Isolated transformer neutral point

## Impedance trajectory

## Asynchronous power swing

(red = active power P; blue = reactive power Q)

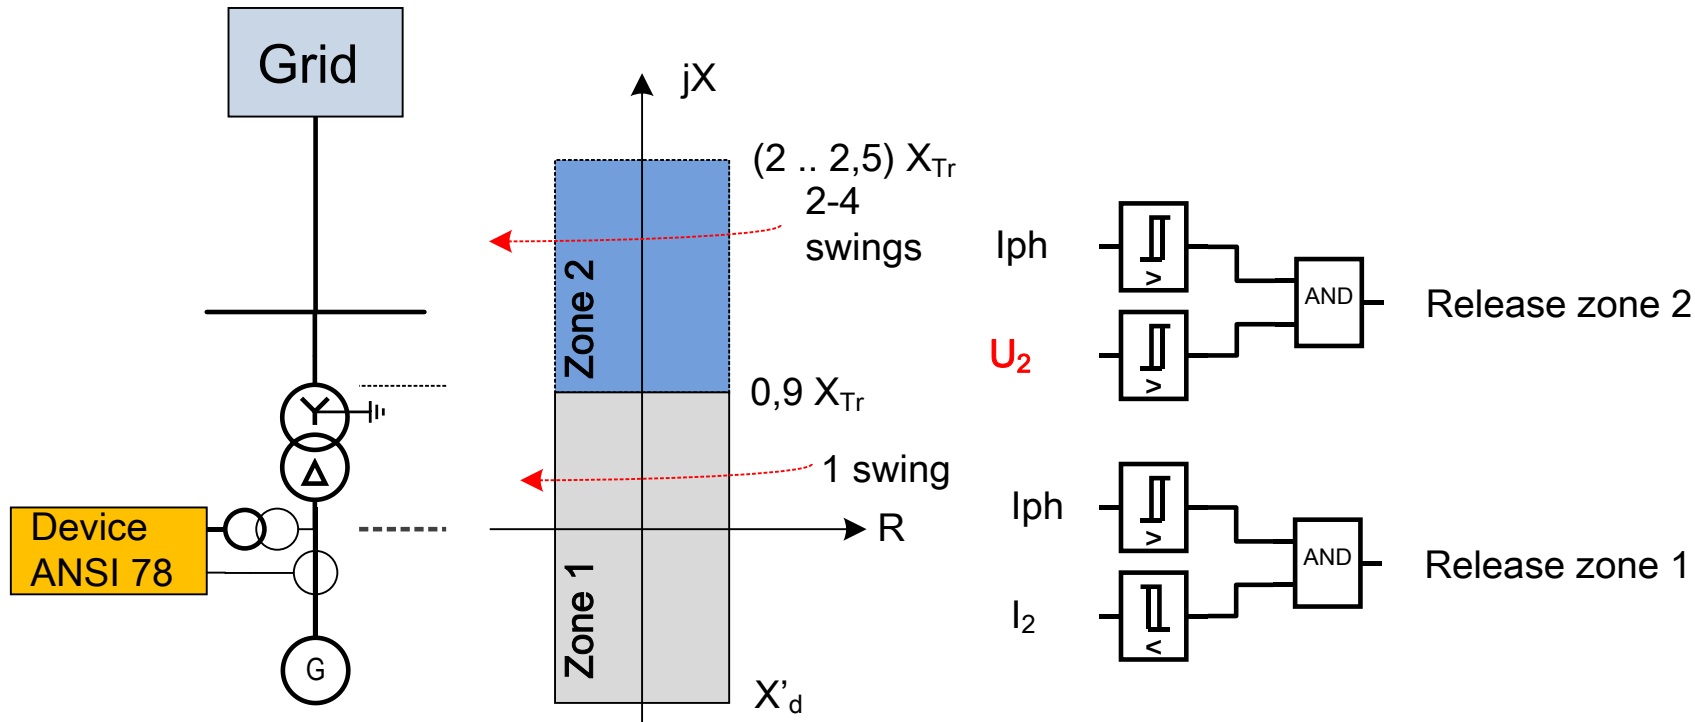

Synchronous swing

Asynchronous swing

The generator falls out of step (out of synchronism) and this event stresses the turbine and generator

# Proposed solution

## Additional characteristic for the out of step protection (ANSI 78)

Possible device: **7UM85**

- More zones are possible ( $U_2$  release via CFC)
- Sensitive and accurate measurement of a low negative sequence voltages ( $U_2$ )
- Additional  $U_2$  alarm is possible or  $U_2$  protection function

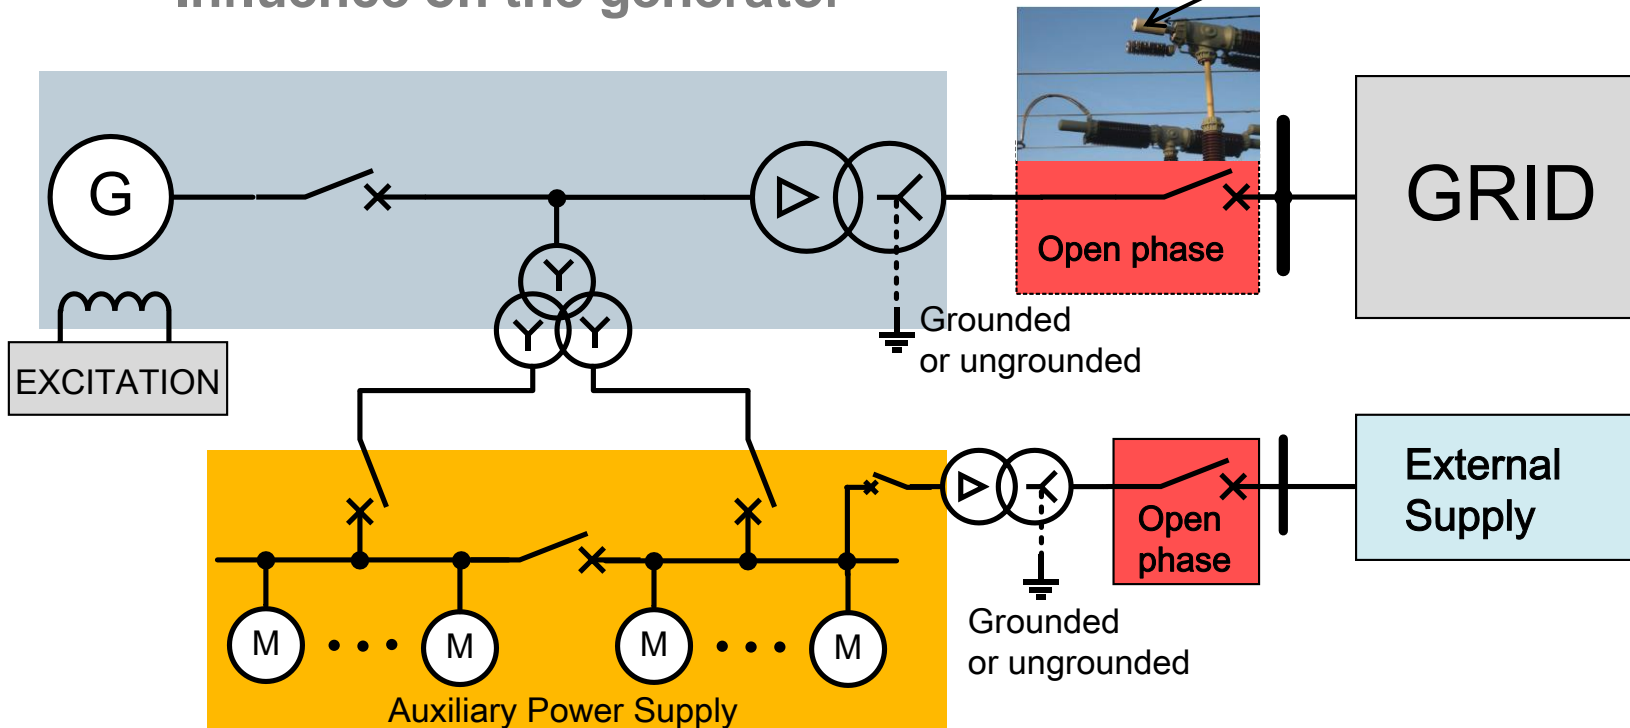

# Power system structure and open phase failure situation

## Influence on the auxiliary power supply

### Two main topics

#### Influence on the generator

Broken connection to the CB

### Byron Failure

## Influence on the auxiliary power supply

## Thermal limits of induction (asynchronous) motors

In the technical data of the induction motor no limits for the negative sequence currents are given. Therefore some tests on motors are done and they showed the robustness of motors.

### Results from a test in the Lab:

- 5%  $U_2/U_1$  (app. 25%  $I_2$ )
- Motor operation 130min
- Winding temperature increased by 12 K
- 50 %  $U_2/U_1$  (app. 150%  $I_2$ )
- Motor operation 60 sec
- Winding temperature increased by 120 K

### Conclusion

**The limits coming more from the protection due to the selected settings**

Given curve from an induction motor:  
 $U_N = 10 \text{ kV}$ ,  $I_N = 108 \text{ A}$ ; Thermal class: F/B

Max. permitted continuous asymmetrical current:  $I_2/I_N = 0.12$

25 %  $I_2/I_N \rightarrow$  allowed time 5 min (300s)

# One open phase failure on the HV-side of the unit transformer

## Summarization of the test results

Simulation cases	Negative sequence voltage ( $U_2$ )	Positive sequence voltage ( $U_1$ )
<u>Grounded</u> unit transformer neutral point; generator in operation	<b>3% to 14% <math>U_2</math></b> (higher value at higher generator load) Synchronous power swing at high load possible	95% to 100% $U_1$
<u>Grounded</u> unit transformer neutral point; generator <u>not</u> in operation	<b>1% to 3% <math>U_2</math></b> (higher value at higher transformer load) → values are close to the operation conditions	approx. 100% $U_1$
<u>Ungrounded</u> unit transformer neutral point; generator in operation	<b>High values of <math>U_2</math></b> (and $I_2$ ), see Figure 11 and 5) Asynchronous operation of the generator is possible	$U_1$ value fluctuates (see Figure 11)
<u>Ungrounded</u> unit transformer neutral point; generator <u>not</u> in operation	<b>15% to 25% <math>U_2</math></b> (normal to high motor load) <b>8% to 15% <math>U_2</math></b> (weak motor load)	80% to 95% $U_1$

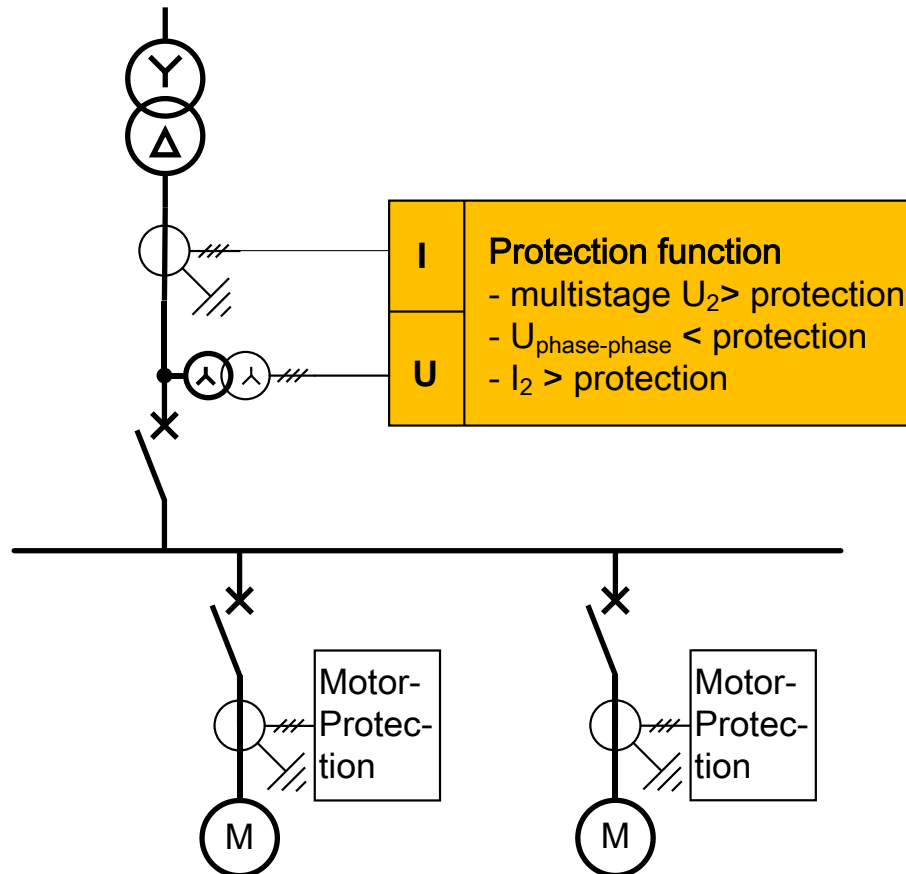

# One open phase failure on the HV-side of the external supply transformer

## Summarization of the test results

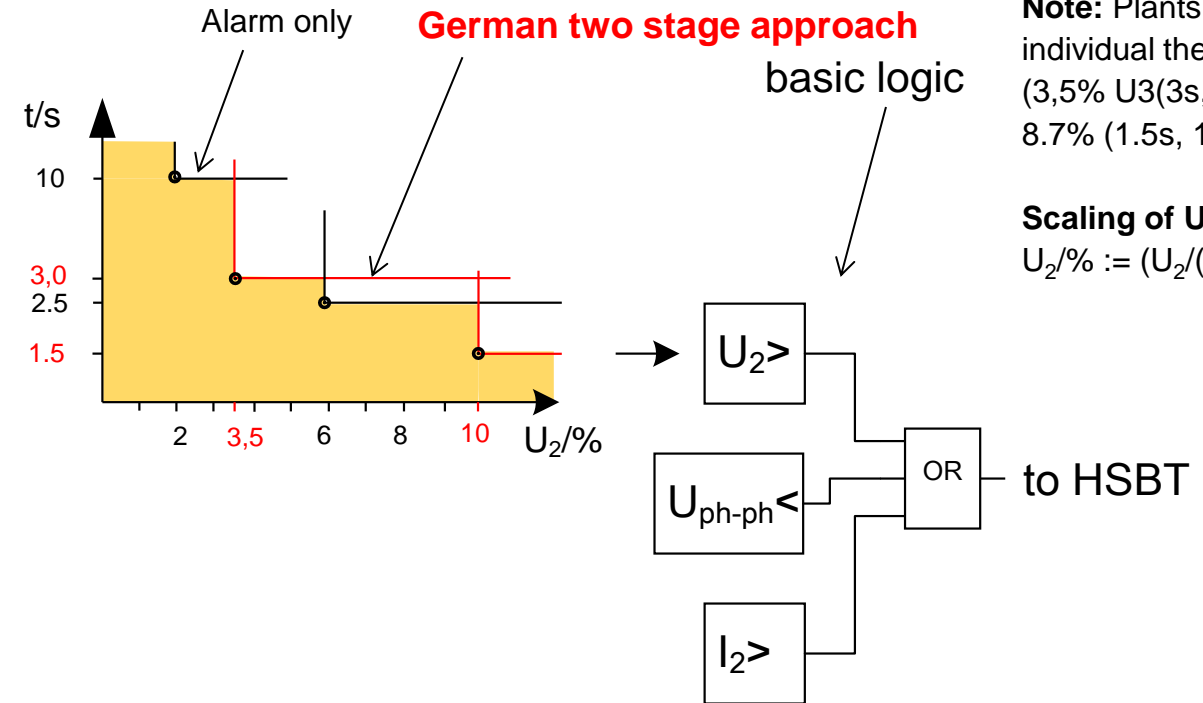

Simulation cases	Negative sequence voltage ( $U_2$ )	Positive sequence voltage ( $U_1$ )
<u>Grounded</u> external supply transformer neutral point; motor load	<b>1% to 6% <math>U_2</math></b> (higher value at higher load)	95% to 100% $U_1$
<u>Grounded</u> external supply transformer neutral point; <u>no</u> load	<b>&lt; 1% <math>U_2</math></b> (not measureable)	Approx. 100% $U_1$
<u>Ungrounded</u> external supply transformer neutral point; motor load	<b>15% to 25% <math>U_2</math></b> (normal to high motor load) 8% to 15% $U_2$ (weak motor load)	80% to 95% $U_1$
<u>Ungrounded</u> external supply transformer neutral point; <u>no</u> load	<b>30% to 70% <math>U_2</math></b> (determined via the coupling, winding capacitances) additional the phase to phase voltages becomes asymmetrical (lower)	40% to 60% $U_1$

# Proposed solution

## Supervision of negative sequence voltage

I	<b>Protection function</b> - multistage $U_2 >$ protection - $U_{\text{phase-phase}} <$ protection - $I_2 >$ protection
U	

**Note:** Plants select individual the settings (3,5% U3(3s, 4s) and 8.7% (1.5s, 1.7s))

**Scaling of  $U_2$ :**  
 $U_2/\% := (U_2/(U_N/\sqrt{3})) 100\%$

- Additional safety criterion is the supervision of the phase to phase undervoltage (setting must be lower then the reduced voltage during motor start; time grading according max.  $U_2$ -time (3s))
- At high motor load  $I_2 >$  stage can be used additional (short time grading, lowest  $U_2$  time)
